A Study of Late Babylonian Planetary Records

Louise Anne Hollywood
MSc Thesis
2002

Abstract

Observations of planets within the Late Babylonian Astronomical Texts record passages of the planets by reference stars, and synodic phenomena such as first visibilities, stations, etc. known "Greek-Letter phenomena". In addition to acting as useful shorthand, use of the Greek-Letter designations for these phenomena allows us to avoid the problem of the exact interpretation of these phenomena. For example, Huber has argued that Ω should probably be understood as the first date on which a planet was not seen, rather than the last day on which it was seen. These observations sometimes have a remark about the 'ideal' date when the phenomena was supposed to occur. This often appears with a measurement of the time from sunrise/set to the observed phenomena.

The aim of this thesis is to study two aspects of Babylonian observational astronomy. One is the interpretation of Θ, one of the 'Greek letter' phenomenon, and proving through analysis of the texts that its precise meaning should be understood as acronycal rising as opposed to opposition. The other is to go some way towards finding the system for correcting an observation when a time measurement of the difference in the time between the planet and the sun rising or setting is recorded along with an 'ideal' or 'true' date.

DECLARATION

This study was undertaken between October 2001 and September 2002 under the supervision of Dr J Steele. No part of this work has previously been submitted for a degree in this or any other university. Part of the material presented in this thesis will be published in the following paper:

Louise Hollywood and J.M. Steele, "Acronycal risings in Babylonian Astronomy" (forthcoming).

INTRODUCTION

Mesopotamia is a land that has yet to reveal all its secrets to the modern world. It was left untouched for a thousand years, hidden by dust and sand. Its story regained interest in 1625 after an Italian nobleman, named Pietro della Valle, returned from travelling with an entertaining story of his journey across Mesopotamia. He brought with him bricks from Ur covered with writing, much to the delight of the libraries of Europe. So began a new enthusiasm for the forgotten history of Iraq.

In 1761 the first scientific mission was sent by the King of Denmark to Persopolis and more inscriptions were brought back for study. Many others ensued and soon the treasures of Babylon and Assyria were in the museums of nations around the world[1]. However until 1843 only the visible ruins of Mesopotamia had been examined, the dusty mounds seen so often throughout the landscape were ignored, until the French consul Paul Emille Botta started excavations of these tells.

Expeditions from abroad and Baghdad itself, were soon excavating and examining both ruins and tells, and many more tablets were found and sent back to the libraries in the hope that the symbols on them could be deciphered and the history of the culture more fully understood. By 1848 the Akkadian language was understood, and more thorough translations were now possible.

The tablets are most commonly hand sized and rectangular[2]. They are made of clay that has had the stylised cuneiform inscribed on it and been left in the sun to dry. There are estimated to be around 150,000 tablets in the British Museum, of which at least 3000 are astronomical, and this is only a small fraction of what would have been written.

Between 1895 and 1900 Pinches drew copies of many tablets, which included many astronomical ones, whilst working at the British Museum. Previously, (1880-1952) only drawings by J.N.Strassmaier, made prior to 1893[3], were available and these were only preliminary sketches to be used for identification, classification and later study. This new source of copies also had the advantage that Pinches had often been able to piece together many fragments of the same tablet.

Much work has been done to interpret, translate and decipher the astronomical tablets over the years. The aim of this thesis is to study two aspects of Babylonian observational astronomy. One aspect is the interpretation of Θ, which is one of the 'Greek letter[4]' phenomena observed and predicted by the Babylonians, and proving through analysis of the texts that it should be understood as acronycal rising as opposed to opposition. The other is to go some way towards finding the system for correcting an observation when a time measurement of the difference in rising or setting time compared to the sun is recorded along with an 'ideal' or 'true' date.

CUNEIFORM ASTRONOMICAL TEXTS

The cuneiform astronomical tablets fall into two main categories, mathematical astronomical texts, which are theoretical, and non-mathematical astronomical texts, which contain observations and predictions.

The original classification of texts was made in an article by Sachs (1948) where he studied the 37 texts known at that time. Despite much more new material becoming available these classifications remain valid. The different types of NMAT are astronomical diaries, normal star almanacs, almanacs, goal year texts and planetary texts.

The astronomical phenomena in the diaries are mostly observations; exceptions are entries regarding solstices, equinoxes, and Sirius data, all of which were computed. Observations recorded in the diaries were of lunar six, planetary phases and conjunctions of the planets and moon with the normal stars. Some planetary and lunar data is predicted when the observation could not be made; when this occurs a remark such as "I did not watch" is added. The diaries also contain summaries at the end of each month stating where the planets had travelled with respect to the zodiac. All the dated astronomical diaries are published in ADT.

The almanacs contain lunar three, the planetary phases, positions of the planets at the beginning of each month and subsequent entries into zodiacal signs, the sun and Sirius. The normal star almanacs contain lunar six or lunar three, the planet's phases, Sirius phenomena, solstices and equinoxes, and conjunctions of the planets with normal stars. They both contain the predictions that would be obtained from using the goal year texts. Copies of many almanacs and normal star almanacs are published in LBAT, SSB, and AaB. A handful of English translations have been published by Sachs (1976), Sachs and Walker (1984), and Hunger (1999).

The goal year texts are collected data of phases and conjunctions of the planets with normal stars, lunar six and eclipses. The data is observations for the required year less one characteristic period[5] (see table 1), which could then be used with an appropriate correction to make the almanacs an normal star almanac.

Table 1.	Characteristic period, years
Mars	47 years for conjunctions with Normal Stars
	79 years for Greek-Letter Phenomena
Jupiter	71 years for Greek-Letter Phenomena
	83 years for conjunctions with Normal Stars
Saturn	59 years
Mercury	46 years
Venus	8 years

The planetary texts simply contain observations regarding a specific planet, often arranged in periods appropriate to the planet, i.e. the length of one synodic period. If an observation could not be made due to bad weather, a computed value was entered followed the remark "I did not see it" or "I did not watch"[6]. All known planetary texts have recently been published in ADT V. 5.

It is possible that all the data in the goal year texts and planetary texts was taken directly from the diaries. For the almanacs and normal star almanacs it would have been the data taken from the goal year texts that was then modified and documented. This would have been a lengthy

[5] Synodic period is the interval between successive similar alignments of a celestial body with the sun, e.g. between oppositions.
[6] E.g. ADT V2, 249.

process, as many diaries would have had to be read and sifted through to get the relevant entries to make the new tablet[7].

Knowledge of the general format of the texts is often useful in completing a sentence which is partially broken away. For example in goal year text number LBAT 1220 the month for the entry has broken away. The next entry is for month IV, which could suggest it was month III but using this date to compute the phenomenon generates an incorrect answer, using month II gives the correct answer. This dating is most likely correct as the format of the goal year texts would only have recorded data of interest and not necessarily something for every month.

Mathematical astronomical texts include procedure texts, ephemerides and auxiliary tables. Most known texts are published in ACT. Procedure texts explain the theoretical systems. They do not explain the physical theory behind the schemes but instead explain the numerous mathematical rules for computing the ephemerides step by step.

Auxiliary tables contain the various numerical functions arranged in separate columns which are needed to calculate the ephemerides. The ephemerides are tables of data giving the position of the heavenly bodies at specific moments. For the moon, these are conjunctions and oppositions which occur each month. For the planets they are runs of greek letter phenomenon. They can be used not only to find the position of a body at regular intervals but ultimately to use the available data to predict its motion.

Predictions in Babylonian astronomy were not always of observable events; instead they were meant to be read as possibilities. For example numerous eclipse possibilities were not observed but the scheme for predicting them continued to be used.[8]

LUNAR PHENOMENA

There are two groups of lunar data observed: lunar three and lunar six. Table 2[9] describes lunar six, and lunar three[10] is a similar group being the length of the previous month, the date in the middle of the month when the moon set for the first time after sunrise and the date when the moon was visible for the last time before sunrise.

Table 2. Lunar six.

Name	Meaning
NA	Day when the moon is visible for the first time after conjunction, time between time sunset → moonset.
ŠÚ	Day when the moon sets for the last time before sunset, time between time moonset → sunrise.
NA	Day when the moon sets for the first time after sunrise, time between time sunrise → moonset.
ME	Day when the moon rises for last time before sunset, time between moonrise → sunset.
GE_6	Day when moon rises for first time after sunset, time between sunset → moonrise.
KUR	Day when moon visible for last time before conjunction, time between date and time moonrise → sunrise.

[7] Hunger(1999), 79.
[8] See Steele (2000b).
[9] Steele (2000a), 29.
[10] Hunger (1999), 79.

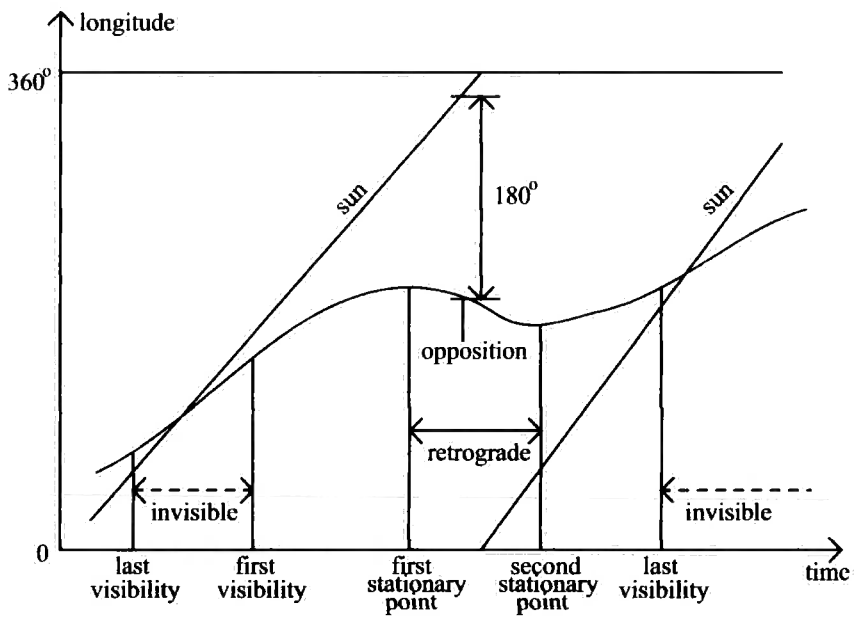
Conjunctions of the moon with normal stars were also observed along with eclipses of the sun and moon. Eclipse accounts would sometimes give various measurements that included timings of the eclipse to sunset or sunrise, its position relative to a normal star, a measurement of the extent of the eclipse in fingers, how long the eclipse lasted and remarks regarding the weather. Predicted eclipses, as found in the A or NSA would simply give the time when the eclipse was supposed to occur.[11]

PLANETARY PHENOMENA

There are several major phenomena of the planets observed by the Babylonian astronomers. These have been termed the 'Greek letter phenomena' and are, for the outer planets[12] (see figure 1):

Γ	first visibility in the east
Φ	first stationary point
Θ	"opposition"
Ψ	second stationary point
Ω	last visibility in the west

Figure 1. Motion of the outer planets.[13]

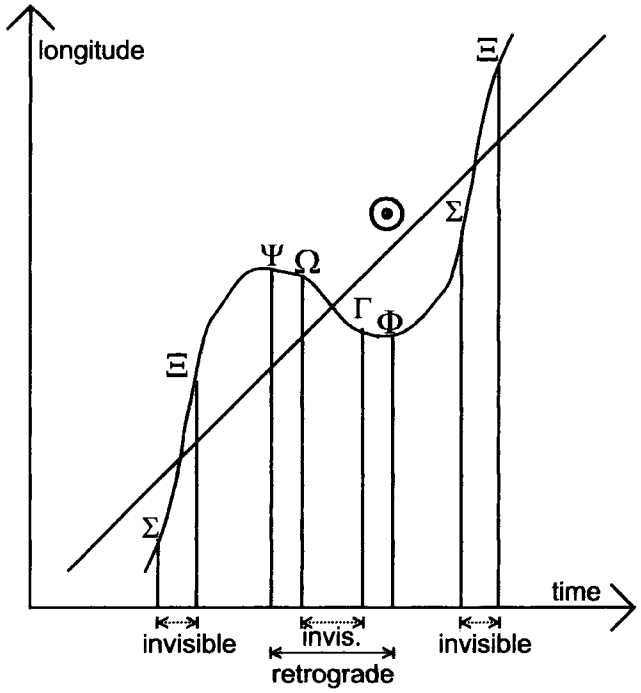


For the inner planets[14] (see figure 2):

Γ	first visibility in the east
Φ	stationary point in the east
Σ	last visibility in the east
Ξ	first visibility in the west
Ψ	stationary point in the west
Ω	last visibility in the west.

[11] See Steele (2000a) for a detailed discussion.
[12] ACT, 280.
[13] Diagram adapted from ACT, 281.
[14] ACT, 280.

Figure 2. Motion of the inner planets.[15]



First visibility in the east is the first day the planet is observed before sunrise. For a planet to be visible the sun must be far enough below the horizon for the sunlight not to overwhelm it and make the planet indistinguishable. This distance is called the *arcus visionus*[16]. A stationary point is when the planet appears to stop in the sky and occurs as the planet "turns" on its retrograde path.

Θ was defined by Neugebauer in ACT[17] to signify an opposition, which is when the sun and planet are 180° apart. This definition would make sense when defining important theoretical phenomena but ancient astronomy is primarily about observed phenomena. With regard to this an acronycal rising, which occurs a few days before opposition and is the first night when the planet rises on the eastern horizon as the sun sets in the west, is just as important. As it occurs so close to opposition it is possible that Θ could signify an acronycal rising.

The *arcus visionus* is less for an acronycal rising than for a first visibility as the planet is brighter at acronycal rising when it is nearer conjunction, and because the eastern horizon is darker in the evening than in the morning.[18]

Last visibility is the day before the planet is too close to the sun to be observable.

NORMAL STARS

Non-mathematical astronomical texts often contain references to fixed stars near the ecliptic in order to provide a more accurate description of a planet's location. Epping[19] originally called them 'Normalsterne' and the term has been used ever since.

Sachs and Hunger (1988) describe their meaning and use:

> In order to give the position of the moon and the planets a number of stars close to the ecliptic are used for reference. ... The Akkadian word for them is MUL ŠID^{meš} ... which seems to means something like "stars of counting, predictable stars"

Sachs (1974) explained their distribution:

> ... the 'conjunctions' of the Moon and each of the planets with some thirty so-called 'normal stars' (i.e. reference stars) scattered about the zodiacal belt are recorded as they occur, and the distance 'above' or 'below' is given in cubits of 2° and fingerbreadths of 5'. ... The reference stars are fairly well distributed in longitude until approximately 230°, after which there is a gap of more than 40°; after about 290° there is an even bigger gap of more than 60°.

THE BABYLONIAN CALENDAR

The Babylonian calendar is made up of 12 lunar months of 30 or 29 days. A new month is signified by the first day when the crescent of the new moon is visible at sunset. At the beginning of any month in the diaries a remark is made as to whether the preceding month was a full month, of 30 days, or a hollow month, of 29 days.

During most of the Late Babylonian period a system of adding 7 intercalary months over 19 years was used[20]. This works because 235 lunar months is almost exactly equal to 19 solar years. The extra month could be a VI_2, second Ululus, or XII_2, second Addarus. Initially deciding whether a VI_2 or XII_2 was added was done empirically, and could be by royal command or by a priest who had noticed that the new month was going to occur at the wrong time – i.e. the moons crescent appeared too early or too late. In later periods intercalations became standardised[21].

The year count until 311BC restarted at the beginning of each new king's reign. 311BC was the start of the reign of Seleucus I, and from this point onwards the year count did not restart and instead simply counted continuously. This is known as the start of the Seleucid Era.

In order to analyse data from cuneiform texts it is necessary to convert the Babylonian dates into Julian dates. This is because any computer program used to obtain the longitudes of planets on specific dates require them to be in the Julian calendar. To convert the Babylonian dates into Julian dates the tables by Parker and Dubberstein (1956) were used. They contain the Julian equivalent for every date from 626BC until AD75.

[21] See Parker and Dubberstein(1956) for further discussion.

MODERN COMPUTATIONS

Part of this study involved the use of computations of planetary and stellar positions using modern theory. A number of computer programs were used for this purpose. For planetary positions, the main two were Steve Moshier's Ephemeris Program V5.1 (1995) AA0, and Kevin Yau's (1989) BRETAGNON which is a Fortran version of a program by Simon for calculating planetary positions using the Bretagnon ephemeris. When calculating the longitude for Sirius, two programs by F. R. Stephenson were used, so that precession could be accounted for.

Precession causes the longitude of a fixed star to increase at a slow uniform rate of 1° in 72.6 years[22], thus over a period of 2300 years this will be an important factor to consider when determining the position of a star. It occurs because the moon causes the earth to have an equatorial bulge. This means that when the earth is spinning its axis of rotation should move in a circle, but because it is oblate it must counteract the force trying to displace it from its spatial orientation. It does this by a precession of its axis and means the earth's axis describes a circle roughly every 26,000 years[23]. It is also important to consider as it causes the equinoctial points to move slowly west with respect to the zodiac.

One consequence of this is the difference between a sidereal year and a tropical year. A sidereal year is the time if takes for the sun to return to a fixed star and is 365.256 days in length. A tropical year is the length of time it takes for the sun to return to the same longitude and is 365.242 days[24].

[24] Aaboe (2001), 21.

THE INTERPRETATION OF Θ AS ACRONYCAL RISING

Babylonian observations of planets fall into two main types: (i) passages of the planets by one of the Normal Stars, and (ii) synodic phenomena such as first visibilities, stations, etc. known "Greek-Letter phenomena".

In addition to acting as useful shorthand, use of the Greek-Letter designations for these phenomena allows us to avoid the problem of the exact interpretation of these phenomena. For example, Ω should probably be understood as the first date on which a planet was not seen, rather than the last day on which it was seen.[25] Nevertheless, it is important to attempt to identify the precise meaning of these phenomena if we are to try to understand the Babylonian observational record and, in particular, its role in the development of mathematical astronomy.

It is not immediately obvious what Θ relates to. It is possible that it is either an astronomical opposition of the planet and the sun, or a nearby phenomenon such as acronycal rising. At opposition the planet is 180° to the sun with respect to the observer, which is difficult to accurately observe as the planet will be low on the horizon and the sky will be too bright. However, an acronycal rising requires the planet to be rising directly opposite the setting sun on the horizon, an easily observable phenomenon since the sky is much darker (see figure 3). There is no exact method to calculate when this occurs as it depends on the observer's eyesight, location, and how the light refracts through the atmosphere[26], but when calculating the difference in longitude between the sun and planet, $\lambda_{\odot}$-λ_{p}, we would ideally expect an acronycal rising to be about 175°, assuming negligible latitude. So a preliminary range of 170-180° would seem appropriate to allow for these variations.

Several statements of the meaning of Θ have appeared in the literature. Epping (1889), p. 113 initially interprets the phenomenon as "opposition of the outer planets with the sun", when listing the phenomena he wishes to discuss:

> b. Opposition der äußeren Planeten mit der Sonne.

But later (p. 135), when discussing opposition, he describes a position where the planet is opposite the setting sun on the horizon:

> Eine bemertensmerthe Stellung am himmel nimmt ein Planet dann ein, wenn er der Sonne gerabe gegenübersteht, oder, was dasselbe ist, wenn er beim Untergange der Sonne ber den horizont sich erhebt.

Kugler (1907) p. 15 also simply translates the phenomena as 'opposition with the sun', in a list of important appearances that demand attention:

> Vor allem fesselten alle jene Erscheinungen ihre Aufmerksamkeit, die von der wechselnden Stellung der Planeten zur Sonne und Erde .....ihre Opposition mit der Sonne, Ihr zweiter Stillstand, und ihr Verschwinden in den Sonnenstrahlen (heliakischer Untergang).

But in Kugler (1909), p. 490 he translates

> 8 AN *aná* ME.E.A

[25] Huber et al. (1982).
[26] Swerdlow (1999), 50.

as

> 8 Mars im akronychischen Aufgang (kurz vor der Opposition)

So translating the *aná* ME.E.A as acronycal rising, remarking that this phenomena is short of opposition.

In an article discussing Sirius phenomena, Sachs (1952), p. 105 writes:

> ... the other is a triplet of dates for the heliacal rising (igi), "opposition" (actually apparent acronycal rising; aná ME (-E) (-A)) ...

Neugebauer (1952), p. 93 stated:

> Disappearance and reappearance of the planets are phenomena close to the horizon and it seems also "opposition" of a planet was defined as rising or setting at sunset and sunrise respectively.

Later, in ACT (1955) he summed up the assumption as:

> All phenomena under consideration, with the sole exception of stationary points, are phenomena in the horizon. This also holds for Θ which we simply call "opposition" but which, in all probability, is "acronycal rising", i.e. rising of the planet at sunset.

Then in HAMA (1975), p. 399 he refers to a translation of Sachs' within a discussion of the procedure texts:

> ...Θ is not the "opposition" in the strict sense of Greek or modern astronomy but that it corresponds to the "*akronycal rising*" of the planet. The planet is then just visible in the east shortly after sunset; the Babylonian term means in fact "opposition in the east." [*Ana* ME-a *ina* kur, or similar (Sachs).]

EVIDENCE FROM THE TEXTS OF MATHEMATICAL ASTRONOMY

Within ACT schemes it has been shown for Mars and Jupiter that Θ occurs closer to closer to Φ than to Ψ which means that Θ has an elongation from the sun of less than 180°. This implies that Θ corresponds to an acronycal rising.[27] Also studies comparing the synodic arc for the planets to the mean sun show Θ falling consistently short of opposition and support the translation of Θ as acronycal rising[28].

EVIDENCE FROM THE TEXTS OF NON-MATHEMATICAL ASTRONOMY

I have collected together all recorded entries for Θ from the available Non-Mathematical Astronomical Texts. For the Diaries and Planetary Texts I have used the editions by Sachs and Hunger (1988, 1989, 1996) and Hunger (2001). Data from the Goal Year Texts was read from the copies by Pinches and Strassmaier in LBAT. For the Almanacs and Normal Star Almanacs, I have collected data from the copies in LBAT[29], AaB, SSB, and editions of individual texts by Sachs (1976), Sachs and Walker (1984), and Hunger (1999).

---

[27] See Hollywood and Steele (forthcoming) for further discussion.
[28] Swerdlow (1999), 58-61.
[29] See appendix for translation of the relevant entries in LBAT.

Before beginning this analysis it is worth noting that the data is limited by those tablets that have survived (and have been published) and is by no means a standardised cross section. Consequently we have an uneven distribution over the years, and for the Almanacs, Normal Star Almanacs and Goal Year Texts we have a very limited number of relevant entries.

EVIDENCE FROM DATA CONCERNING THE PLANETS

A total of 125 usable observations were collected for the outer planets. Of them, most were recorded 400BC-100BC. From the observed dates of Θ the difference in longitude with the sun was calculated. It was seen that nearly all the values for $\lambda_{\odot}-\lambda_{p}$ ranged from 165-195°. There were three exceptions:

Table 3. Erroneous data for acronycal risings.

Source	No.	Planet	Date SE	Date BC	Planet λ	Sun λ	$\lambda_{\odot}-\lambda_{p}$
Planetary text	76	Mars	51 XII 12	260 MAR 21	2.9089	356.797	353.8881
Planetary text	70	Jupiter	22 IX 22	290 DEC 24	41.009	269.02	228.011
Diary V2	253	Jupiter	58 IX 29	254 DEC 23	62.67977	268.2545	205.5747

The entry for Mars, which came from a planetary text, is written with the remark "around, I did not watch". This would imply that the number was calculated. However, for it to be so far beyond what is expected would suggest that there was either an error in the calculation or that the record contains a scribal error. For example if the year was SE52 then $\lambda_{\odot}-\lambda_{p}$ =175.8 which is what we would expect for an acronycal rising.

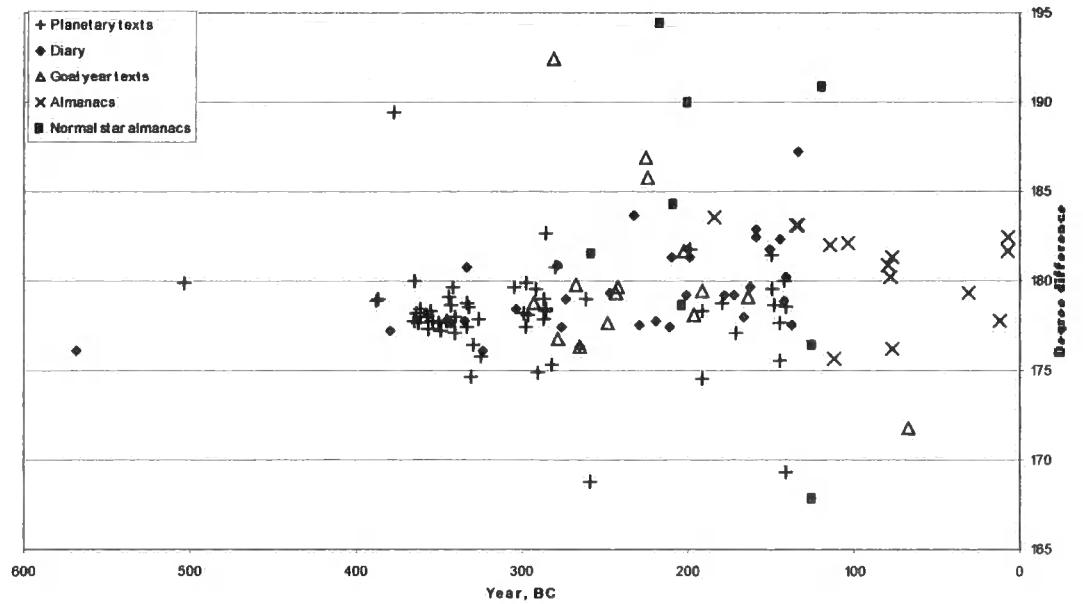
The two entries for Jupiter did not have an attached comment; however, for the entry from a diary the end of the sentence was broken away. These may also therefore be scribal errors.

Examining the data first by source (figure 3) it is clear that there is a large variation in the number of different types of text. The overall spread of the data from the various sources is based around 180° but on initial inspection it is clear that this spread varies greatly with each source.

Table 4. Acronycal risings data with respect to source.

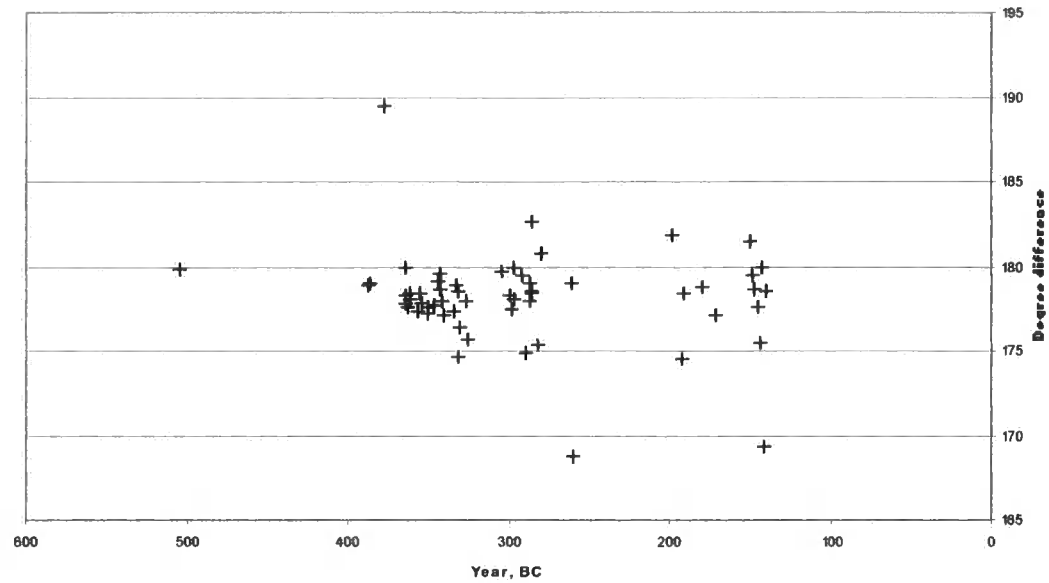
Source	Average	Standard Deviation	No. records
Planetary texts	178.1	2.8	58
Diaries	179.2	2.0	35
Goal year texts	178.1	9.9	16
Almanacs	180.7	2.5	14
Normal star almanacs	183.0	8.8	8

Figure 3. All the data divided into sources.



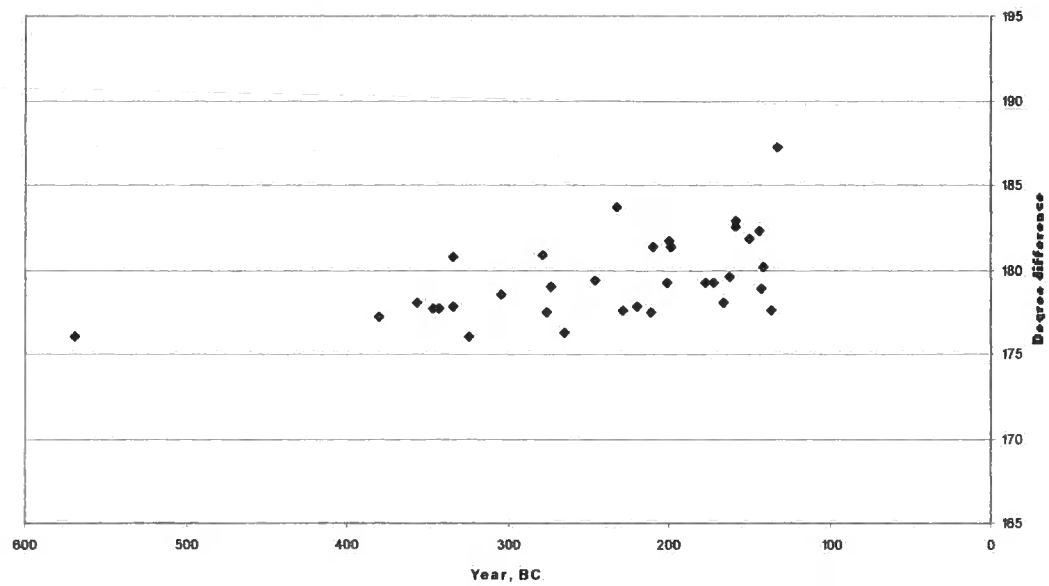
The largest proportion of the data was abstracted from planetary texts (Figure 4) something to be expected since they are compilations of such datum, and ☿ would have been one of the phenomena of note. The data was mainly distributed from 390BC – 140 BC, with one point from around 500BC in one of the oldest planetary tablets. The planetary data shows most of the points have elongations below 180°. This would appear to confirm an acronycal rising and is one of the more reliable results due to the relatively large amount of source data.

Figure 4. Data from the planetary texts.



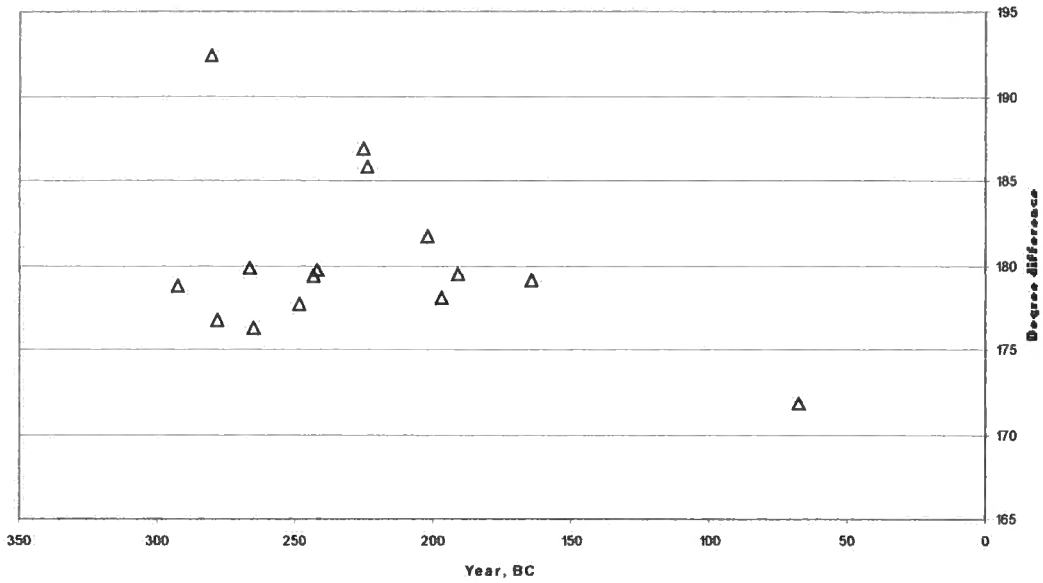
The entries for the diaries (Figure 5) ranged 176-187°. This data was spread from 390BC to 140BC with one point from 580BC, found in one of the oldest diaries known to date. The average is just within what we would expect for an 'acronycal rising' but since about a third of the points are above 180° this result is not irrefutable.

Figure 5. Data taken from the diaries.



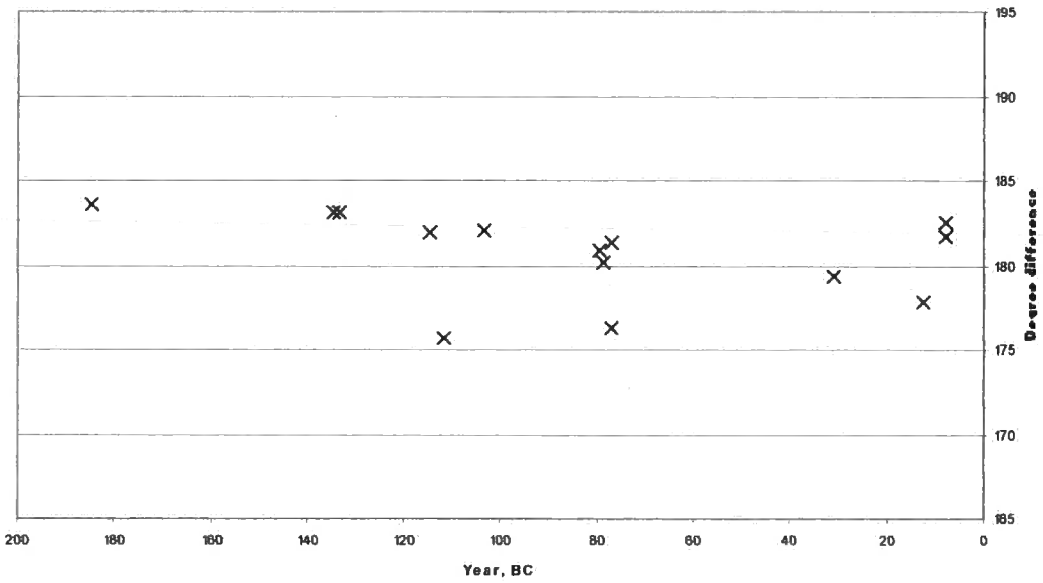
For the goal year texts (Figure 6), the data is spread from 293BC to 67BC. Two thirds of the points are between 176° and 180° which is what we expect for an acronycal rising. However the other points vary widely, from 171-192°, so this result is not conclusive.

Figure 6. Data from the goal year texts.



For the almanacs (Figure 7) the data ranged in date from 184BC to 7BC, and in elongation from 175-184°. They are not widely spread, and the average of 180.7 is on the boundary of our limiting range.

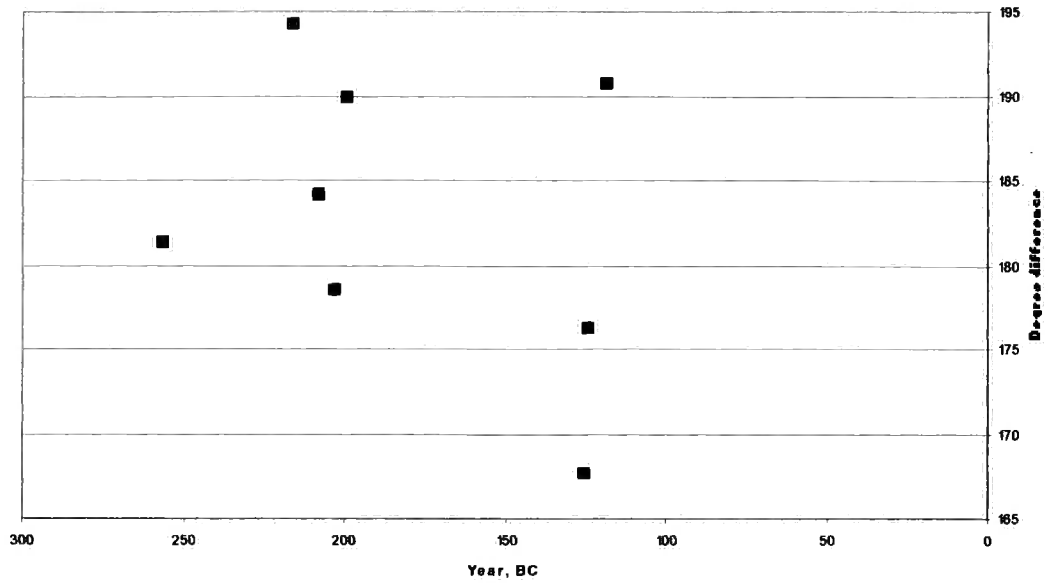
Figure 7. Data from the almanacs.



In the case of the normal star almanacs (Figure 8) no results can be drawn since the data ranges 167-194° with only 7 points.

The lack of data for the almanacs and normal star almanacs is due to the fact that there are not very many large tablets available. The ones that have survived are fragmentary and thus a degree of luck is necessary to acquire the relevant information.

Figure 8. Data from the normal star almanacs.



Overall it is clear that due to the lack of data in other sources, conclusions can only be drawn for the diaries and planetary texts. The majority of their points are below 180°, and although the averages are quite high, for an opposition we would expect an even distribution above and below 180°. For these two sources it would therefore appear that Θ does in fact mean acronycal rising.

Examining the data with respect to which planet is being observed, again there is a definite bias. It is also clear that the range for each planet varies resulting in different averages.

Figure 9. All the data divided into planets.

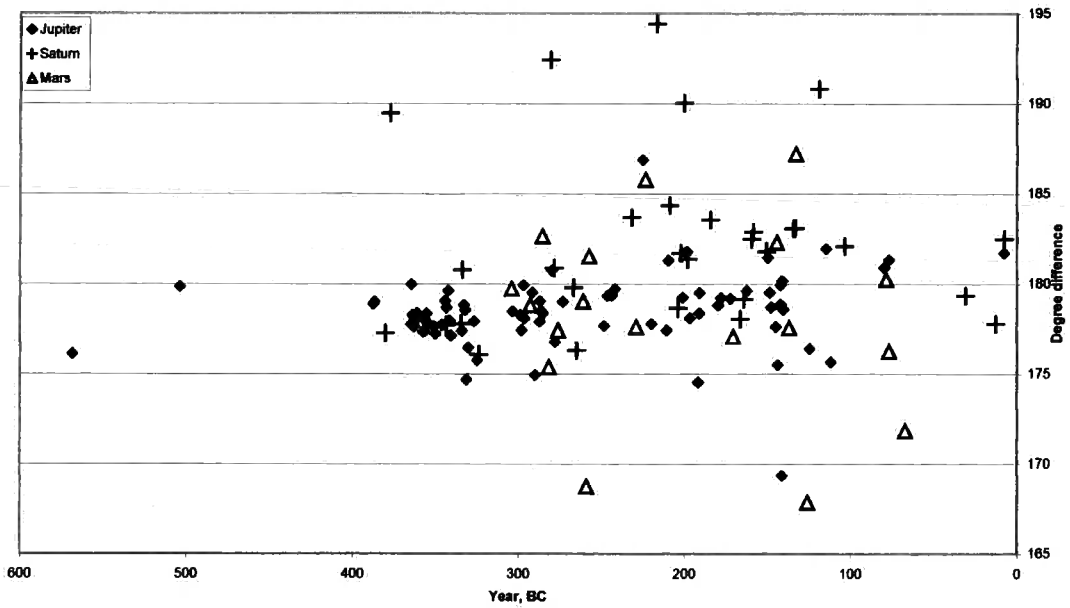


Table 5. Acronycal risings data with respect to planet.

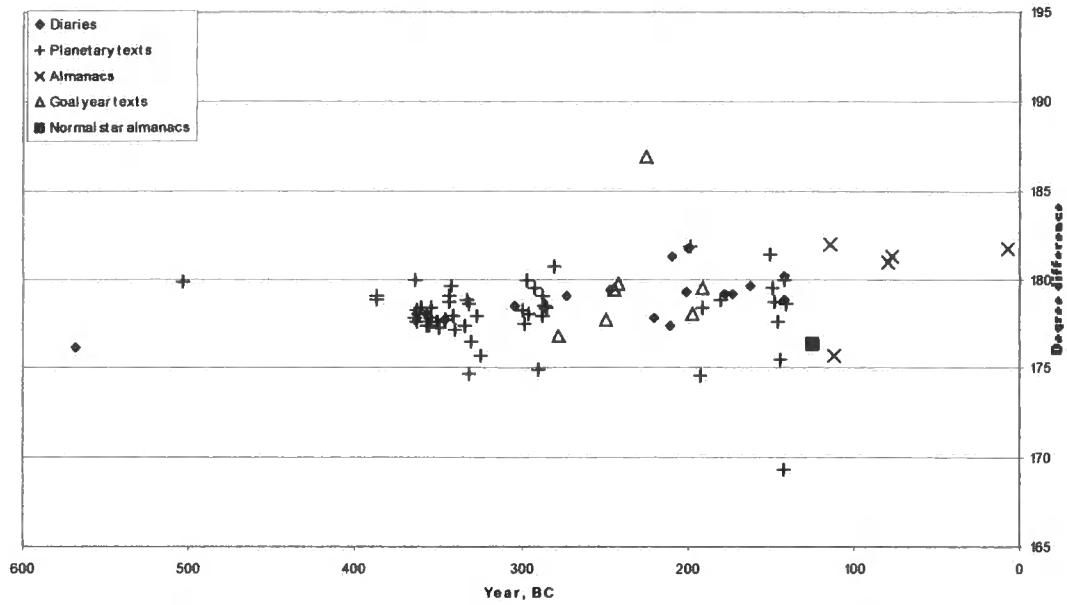
Planet	Average	Standard Deviation	No. observations
Jupiter	178.1	4.2	82
Saturn	182.1	4.8	31
Mars	178.2	5.1	18

Figure 10. Data for Jupiter



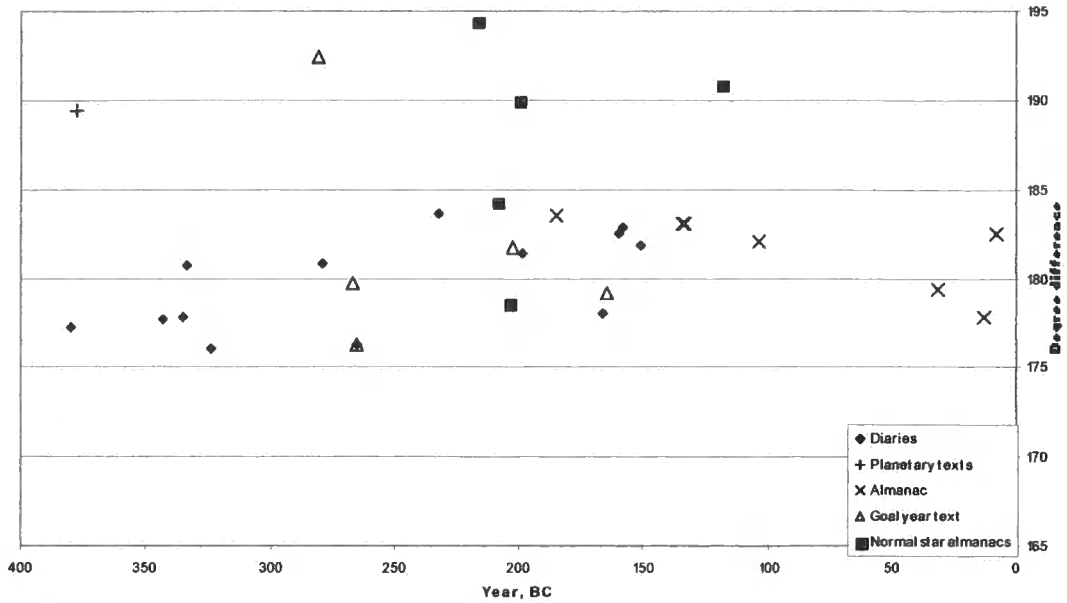
The data for Jupiter ranges mainly from 175-182°, distributed between 580BC to 10BC. As shown in the figure 10 most of the entries - more than 60% in fact - originate from the planetary texts. This is to be expected since the planetary texts were compilations of the astronomical entries from many diaries for each planet - unlike a fragment of a diary, for example, which could also contain remarks relating to the weather or military events. Despite the large amount of data for Jupiter, it is not widely distributed, and with an average of 178.1° it would seem to indicate an acronycal rising.

For Saturn (Figure 11) the data was from 390BC to 10BC and was more widely spread out than for Jupiter. However most of the data is still above 180°, resulting in a large average of 182° which would seem to suggest that the measurement was not for an acronycal rising, where we would expect 175-180°. Whilst it could mean that 'acronycal rising' should be 'opposition', it should be remembered that for each source of datum the values are very different. The data from the diaries is mainly distributed around 180°, whereas the normal star almanacs data are based around 185°.

This is almost certainly a result of how the data was calculated for the normal star almanac. If the correction to the goal year period is too large, i.e. a late prediction, it will give a larger $\lambda_{\odot}$-λ_{p}. According to Hunger (1999), by modern theory the calculation should be the addition of one synodic period less 6 days. When he compared the goal year texts to the normal star almanacs he found a range of differences, from –1 to –13 days. Where the correction is less than 6 days, which he found was often the case, the phenomenon will occur too late and Saturn's elongation will be greater than that expected for an acronycal rising.

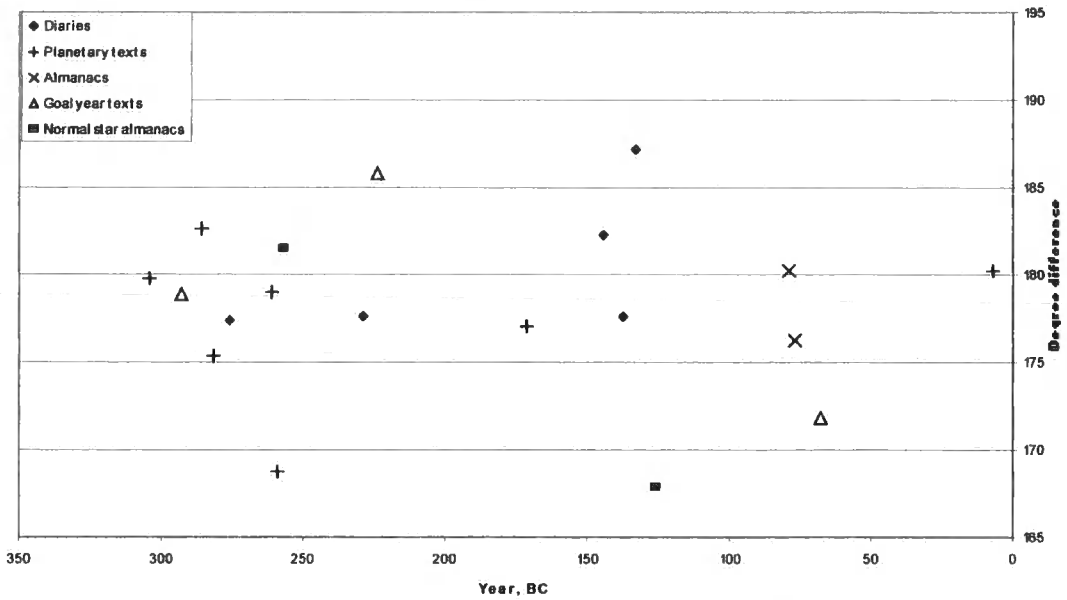
The fact that Saturn's elongation at Θ is greater for the predictions in the normal star almanacs than the observations in the diaries, confirms that too small a correction to the goal year period was often applied. It also indicates that the goal year periods were in actual fact used to compile the normal star almanacs.

Figure 11. Data for Saturn.



For Mars (Figure 12) the data dated mainly from 304BC to 7BC, ranging in elongation 167-187°. The data is very widely distributed, however the diaries cluster around 180°, with the normal star almanacs having the lowest longitude difference. Nevertheless the average is 178.26° which is within the preliminary boundaries we have set, but with such a large variation in the data it can by no means be considered conclusive.

Figure 12. Data for Mars.



For the planets it would at first appear that there is a problem with Saturn, since the average is over 180°, but even though there are numerous datum points they come from various sources, and the values from the normal star almanacs are extreme. Thus for Saturn the results can be explained and still prove the case for ☉ being an acronycal rising. It is also evident that the results for Jupiter will be the most confident since it has by far the most amount of data. It has a reasonable average and a low standard deviation, and indicates an acronycal rising.

SIRIUS

The data for Sirius was obtained from the diaries and the almanacs, with A.Sachs collecting the latter in his 1952 article. In this study it is Sachs' compilation of raw datum that was used.

Since all but one of the Sirius entries was calculated, it is essential to examine them separately from those for the planets. The diaries used schematic dates for the characteristic phenomena of Sirius since around 330BC, with only occasional observations recorded. Likewise the solstices and equinoxes were calculated from this date – unsurprising given that they are needed to calculate Sirius phenomena.

Since Sirius is located a long way from the ecliptic it has quite a large negative latitude, about -37° for the years with the necessary data. This forces the characteristic phenomena of Sirius to occur in an abnormal order. That is with acronycal setting, Θ_2, falling on an earlier date than acronycal rising, Θ_1. Thus the order of phenomena is Ω to Γ to Θ_2 to Θ_1[30]. Since Θ_2 occurs before Θ_1, the elongation for an acronycal rising will in fact occur with an elongation greater than 180°, and acronycal setting less than 180°.

The system for calculation, as established by Sachs (1952) is

Γ = SS + 21 tithis[31]

Ω = SS – 44 tithis

Θ = SS + 191 tithis

This scheme works in conjunction with a scheme for determining solstices discovered by Neugebauer (1947). It must also be remembered that this scheme is made assuming all months contain 30 days, therefore if the previous month has 29 days then the phenomena should occur a day later.

This means that for a nineteen-year cycle the schemes are:

	SS	AE	WS	VE
1	III 18	VI 21	IX 24	XII 27
2	III 29	VII 2	X 5	XII_2 8
3	III10	VI 13	IX 16	XII 19
4	III 21	VI 24	IX 27	XII 30
5	IV 2	VII 5	X 8	XII_2 11
6	III 13	VI 16	IX 19	XII 22
7	III 24	VI 27	IX 30	I 3
8	IV 5	VII 8	X 11	XII_2 14
9	III 16	VI 19	IX 22	XII 25
10	III 27	VI 30	X 3	XII_2 6
11	III 8	VI 11	IX 14	XII 17
12	III 19	VI 22	IX 25	XII 28
13	III 30	VII 3	X 5	XII2 9
14	III 11	VI 14	IX 17	XII 20
15	III 22	VI 25	IX 28	I 1
16	IV 3	VII 6	X 9	XII_2 12
17	III 14	VI 17	IX 20	XII 23
18	III 25	VI 28	X 1	I 4
19	IV 7	VI_2 9	IX 12	XII 15

Table 6. Solstice and equinox dates for the Sirius cycle.

	Γ	Θ	Ω
1	IV 9	IX 29	II 4
2	IV 20	X 10	II 15
3	IV 1	IX 21	I 26
4	IV 12	X 2	II 7

[30] See HAMA, 1091.

[31] 1 tithi= $^1/_{30}$ month

The Uruk solstice scheme was recently re-examined by Slotsky (1993). In the original scheme reconstructed by Neugebauer he determined that each successive solstice date was found by adding 11;3,10 tithis, but the scheme rounded this to 11 for convenience. This meant that due the accumulation of 0;3,10 tithis 11 days must be added each year, in the form of hollow and full months, except in years with an intercalary Ululu where 12 days were added.

Another inaccuracy, which is due to the difference between the approximation of 1 year to 12;22;6,20 months which is too long by 0;0;10 tithis when compared to the cycle of 19 years to 235 months, was determined by Neugebauer to accumulate to one full day in SE113, thus the scheme would require the solstices to be one day earlier from that date, i.e. SS became IV 6, for years with an intercalary Ululu.

However Slotsky found evidence to the contrary. In BM 36811 which is an undated astronomical text, but is pre SE113, she found that years which contained 2-Ululu the summer solstice continued to be on IV7. Then in a diary from SE 56 which contains month 2-Ululu, the autumnal equinox is on VI** 10, which is consistent with the post SE 113 scheme. Thus there is no divergence at SE 113 and dates before this with a 2-Ululu calculated by the Uruk scheme must be disregarded.

Comparing the Uruk scheme to the 31 entries collected, taking a date for the scheme as SE 56, shows that the data corresponds exactly in all but 2 cases.

One is the oldest entry, from 384BC, which differs by 2 days and is observed according to the diary. This is acceptable since the diaries did not start consistently using the computed values until 330BC.

Another entry, from SE151, was taken from a translation by Sachs of an unpublished tablet. In it he has written the month as [IX] indicating how he had to fill in this data himself. In order to fit with the scheme, however, we require it to be month X, something which is probably attributable to a scribal error either on the tablet or in the translation.

A tablet from Uruk translated by von Weiher (1998)[32] describes an alternate scheme. It does not mention Θ but does have Γ which is one tithi earlier than in Sachs' scheme. This scheme does not fit with our data but it still shows that several schemes were available.

Of our data collected (shown in table 8) shows that $\lambda_{\odot}$-λ_{Sirius} ranges from 203-207°. The data varies only over 4° in 300 years, which could be expected since Sirius does in fact move along the zodiac, although very slowly, less than 3° in 300 years.

These values match with what we would expect for Θ_1 for Sirius.

[32] See also ASM and Britton (2001).

[33] SBA means Sachs (1952).

IDEAL DATES OF PLANETARY PHENOMENA

Amongst observational records there are often comments regarding an unexpected observation or not observing a phenomenon that was expected. Hunger and Pingree[34], mention within a discussion of planetary theory in Enūma Anu Enlil where they refer to a previous publication of Reiner-Pingree (1981):

> Two commentaries on tablets relating to Tablet 50 ... ... refer to the planets passing by their specified times (UD.SUR of adannu) and not rising promptly, or to the planets not completing their days and setting promptly.

Within descriptions of a planet's first or last visibility there is sometimes a remark made about the 'ideal' date when the phenomenon was supposed to occur. This often appears with a measurement of the time from sunrise/set to the observed phenomenon. For example:

> 10 GU_4-UD *ina* ŠÚ *ina* UR-A 3 KÙŠ *ina* IGI *dele-bat ana* ŠÚ IGI 16 [*na-su in* 8 IGI]
>
> The 10th, Mercury's first appearance in the west in Leo, 3 cubits in front of Venus to the west; sunset to setting of Mercury:16°; [(ideal) first appearance on the 8th.][35]

Swerdlow (1998), p. 44 describes this "ideal" or "true" date being corrected according to the timed measurement, but where this measurement is small no correction is necessary:

> As proposed by Hunger, certainly correctly, the ideal date was inferred from the time of visibility between rising and setting of the planet and the sun; if this was over some amount, the true first appearance must have been earlier and last appearance later than the observed by some number of days, although the method of computation, of inference, is not clear, and as would be expected, the times of visibility in the reports without an ideal date seem to be shorter.

In Swerdlow (1999) he claims:

> dates of heliacal risings were used to establish synodic times since, through the use of rising times to determine the 'true' date, they appear to have been the most carefully observed.

Again Hunger and Pingree[36] remark about this, in a chapter concerning the planets:

> Often, if the interval appears to the observer to be too long, he notes that the phenomenon should have been visible on a previous night or that it will be seen on a later night with the words: "(ideal) first (or last) appearance on the nth." For the superior planets we are sometimes given the time degrees between Γ and sunrise or sunset and Ω; ... ... A careful study of such observations might reveal the criteria that the Babylonians used to estimate the "ideal" dates of the phenomena.

It is the aim of this study to go some way towards finding that criterion.

[36] ASM, 145.

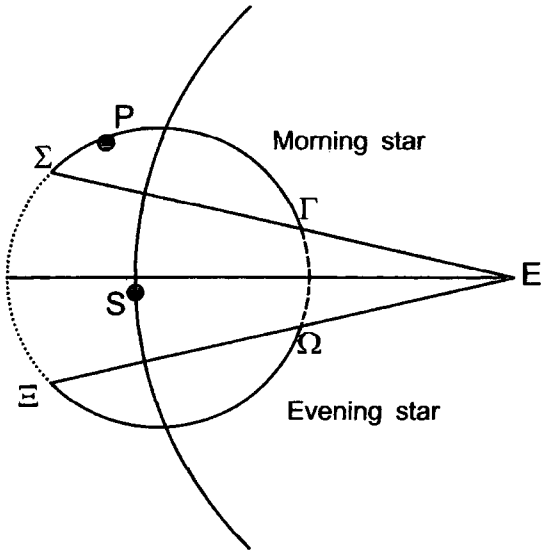

Figure 13. For the inner planets. A planet has a period of invisibility when it is above the horizon the same time as the sun. First visibility is the first day the planet is far enough away from the sun that it rises long enough before sunrise to be seen. Last visibility is the last day before the planet is too close to the sun to be observable.

Γ, Σ, Ξ and Ω are 'Greek letter phenomena' used to describe how a planet moves (see figure 13[37]). There are schemes for predicting these phenomena described in ACT. For each planet there are often several schemes that are used, falling into two main types known as system A and system B. Both are based on variation of velocity and specify that the phenomenon moves through synodic arc $\Delta\lambda$ in synodic time ΔT. System A has the synodic arc as a step function of longitude, the velocity having fast and slow zones. In system B the synodic arc is a zigzag function of the number of times the phenomenon has occurred in the ACT period resulting in a continuously varying velocity.

First and last visibilities have many factors that cause them to be non-specific phenomena, i.e. there is no exact condition for $\lambda_{\odot} - \lambda_{p}$. Instead, the planet's elongation varies according to latitude, brightness of the planet (the brighter it is the shorter the period of invisibility), inclination of the ecliptic to the horizon (the smaller the inclination the further the sun must be from the star or planet to be visible), and atmospheric conditions. For example, a person observing on the equator would see the sun would rise earlier than someone further north, thus Γ would occur on a different day, even if all other factors were constant.

However, it is expected that the 'ideal' date was not calculated by any known system in ACT, as a time measurement was included within the entries and no system within ACT uses a time measurement. Whenever an entry is found without a time measurement it was often due to a break in the tablet or because the entry was recorded in the summary at the end of the month.

To investigate this issue, 'ideal' information was collected from the diaries, planetary texts and goal year texts. We would not expect to find any from the almanacs or normal star almanacs since they contain theoretical data and the 'ideal' data is obviously an observation of a phenomenon that occurred outside a predictive scheme.

The majority of the data was found for Mercury, with only 63 complete records found for the other planets combined. In analysing the data it is necessary to consider each phenomenon separately since the time measurement for each will be for a different period, for example rising of a planet to sunrise for Γ, but sunset to setting of a planet for Ξ. As a result the analysis mainly focuses on Mercury for whom more dependable deductions could be made.

[37] Adapted from Neugebauer (1952), 120.

Because of the scarcity of data for the other planets, their analysis has been done by combining all of the available data including Mercury. Thus it may only be relevant to the extent of seeing a general trend with relation to the zodiac. No specific results could be gleaned as each planet has several schemes to calculate 'Greek letter' phenomena, and it is to be expected that each planet would again have a different scheme for calculating an 'ideal' date from a time measurement.

Before looking at the observational data obtained from the diaries it is worth considering the theoretical systems. Obviously for there to be a need to correct the observation there was something 'wrong' with it. Initially we could suggest it was either to high in the sky and required a correction, or it did not fit in with the theory.

Theoretical Schemes for Calculating Mercury Phenomena

For Mercury there are three separate methods currently known for calculating ephemerides.[38] For the first system, A_1, first visibilities Γ and Ξ, are computed independently and the period of visibility is added to find last visibilities Σ and Ω. A_2 is the reverse of this, in that the first visibilities are functions of the last visibilities. For system A_3, Γ, Ω and Ξ are all independent phenomena, but the procedure text that describes this system says nothing about Σ. This system only occurs in one procedure text and much has had to be reconstructed so less is known about it.

All three of these systems work on the basic premise that for Mercury, 145 occurrences of the same phenomena occur in 46 years. The systems are all are of type A and so use step functions of the position in the ecliptic. There are variations between each system due to distributions of the zones for each phenomena. However non of the systems use the time difference between the setting of the sun and rising of Mercury within the method.

Each first and last visibility does in fact have slightly different periods to the general one shown above. These are

Γ	2673 appearances in 848 years
Σ	1223 disappearance in 388 years
Ξ	1513 appearances in 480 years
Ω	684 disappearances in 217 years[39]

But these differences would not be noticed unless several centuries of data were examined.

System A_1

For system A_1 the procedures are as follows.

For Γ	From Leo1 to Capricorn 16	w_1 = synodic arc = 1,46°
	From Capricorn 16 to Taurus 30	w_2 = 2,21;20°
	From Gemini 0 to Leo 1	w_3 = 1,34;13,20°

The correction for going between

zones 1 to 2 = 0;20
zones 2 to 3 = -0;20
zones 3 to 1 = 0;7,30

For the date the synodic time is

$\Delta_n\tau = (\Delta_n\lambda + 3;30,39)^\tau$ where τ means the unit of a tithi= $^1/_{30}$ month.

For Ξ	From Cancer 6 to Libra 26	w_1 = 2,40°
	From Libra 26 to Pisces 10	w_2 = 1,46;40°
	From Pisces 10 to Cancer 6	w_3 = 1,36°

Which makes the correction for going between

zones 1 to 2 = -0;20
zones 2 to 3 = -0;6
zones 3 to 1 = 0;40

The synodic time for the date is the same as for Γ.

[38] See ACT II for a full description of these systems.
[39] ACT II, 288.

To show how this works in practice we will take an entry from one of the ephemerides and use this system A_1 on it to obtain a new position which we can then check with the ephemeris.

From ACT no.300[28] line 35 we read a position for Γ of Capricorn 26;20 with date 2,8 XI 3;33,11.

First for the position: We are in zone 2 so we add w_2 to our position to obtain Capricorn 2,46;40 which is in fact Gemini 17;40 as there are 5 lots of 30 so we travel through 5 signs.
Now we need the difference between the end of this zone and our position to multiply by the correction for crossing zone 2 to 3.
This is 17;40 * -0;20 = - 5;53,20.
We now add this to our preliminary position of Gemini 17;40 to obtain a final position of Gemini 11;46,40.
This can now be checked against the next line in the text which reads 11,46,40 Gemini Γ, and shows we have done our workings correctly.

For the date we need the difference between the first position on line 35, and the next position which we have calculated. This difference is the synodic arc and is equal to 2,15;26,40°.
To this we add 3;30,39ᵀ to obtain the synodic time 2,18;57,19ᵀ which is equivalent to 4 months + 18;57,19ᵀ.
We now add synodic time onto our original date and arrive at our final date of 2,9 III 22;30,30ᵀ.
This is in agreement with the text.

In System A_1, for the last visibility positions and dates an amount Δ is added to the first visibility. The amount Δ varies according to its position in the zodiac: In the following table,[40] the values are given for 15° of each sign, i.e. the middle, and to find Δ for positions in between you must simply use linear interpolation.

	Δ = B(Σ) – B(Γ)		Δ = B(Ω) – B(Ξ)	
	For 15°	Interpolation to next sign	For 15°	Interpolation to next sign
Aries	12	+ 0;4	36	+ 0;12
Taurus	14	+ 0;8	42	+ 0;8
Gemini	18	+ 0;8	46	- 0;8
Cancer	22	+ 0;8	42	- 0;12
Leo	26	+ 0;8	36	- 0;28
Virgo	30	+ 0;8	22	- 0;16
Libra	34	+ 0;20	14	0
Scorpio	44	0	14	+ 0;4
Sagittarius	44	- 0;4	16	+ 0;8
Capricorn	42	- 0;16	20	+ 0;4
Aquarius	34	- 0;20	22	0
Pisces	24	- 0;24	22	+ 0;28

[28] ACT III, 156.
[40] ACT II, 293.

	$\Delta = T(\Sigma) - T(\Gamma)$		$\Delta = T(\Omega) - T(\Xi)$	
	For 15°/ᵀ	Interpolation to next sign	For 15°	Interpolation to next sign
Aries	14	+ 0;4	36	+ 0;12
Taurus	16	+ 0;6	42	+ 0;12
Gemini	19	+ 0;10	48	- 0;8
Cancer	24	+ 0;6	44	- 0;12
Leo	27	+ 0;6	38	- 0;36
Virgo	30	+ 0;12	20	- 0;10
Libra	36	+ 0;20	15	0
Scorpio	46	0	15	+ 0;2
Sagittarius	46	- 0;4	16	+ 0;12
Capricorn	44	- 0;20	22	+ 0;4
Aquarius	34	- 0;20	24	0
Pisces	24	- 0;20	24	+ 0;24

An example to find a position for Σ will be the same method to use to find any position of time for Σ or Ω.
On line 27 of no.302 column VI we have the position Virgo 20;45. This is equivalent to Virgo 15 + 5;45.
The correction from the interpolation is now 5;45 * 0;8 = 0;46.
Thus we have B(Σ)- B(Γ) = 30 + 0;46 = 30;46.
So B(Σ) = Virgo 20;45 + 30;46 = Virgo 51;36 = Libra 21;31.
To check this result we have to look at the same line but in column VIII where we see we have the same answer.

The other two systems or Mercury work in a similar fashion and are outlined below.

SYSTEM A_2.

For Σ	From Pisces 0 to Virgo 30	$w_1 = 1,47;46,40°$
	From Libra 0 to Capricorn 6	$w_2 = 2,9;20°$
	From Capricorn 6 to Aries 5	$w_3 = 1,37°$
	From Aries 5 to Gemini 30	$w_4 = 2,9;30°$

Which makes the correction for going between
zones 1 to 2 = 0;12
zones 2 to 3 = -0;15
zones 3 to 4 = 0;20
zones 4 to 1 = -0;10
For the date the synodic interval is
$\Delta\tau = \Delta\lambda + 3;30,39^{\tau}$

For Ω	From Pisces 0 to Sagittarius 30	$w_1 = 1,48;30°$
	From Virgo 0 to Aquarius 30	$w_2 = 2,0;33,20°$
	From Pisces 0 to Aries 30	$w_3 = 1,48;30°$
	From Taurus 0 to Gemini 30	$w_4 = 2,15;37,30°$

The synodic interval for the date is the same as for Σ.

For Ξ there are few tablets with a complete scheme. The following is reconstructed from no.300 and does not cover Aries to Taurus or Leo to Virgo. Nevertheless it is known that B(Ξ) is found by adding an amount to B(Σ) which relies solely on the planets position in the zodiac.

For Pisces $0 \leq \lambda \leq$ Sagittarius 20 $\quad B(\Xi) =$ Sagittarius 18;30 + 0;45*(λ - Pisces 0)
For Sagittarius $20 \leq \lambda \leq$ Aries 20 $\quad B(\Xi) = \lambda + 58;30$
For Gemini $0 \leq \lambda \leq$ Cancer 30 $\quad B(\Xi) =$ Cancer 15 + 1;30*(λ - Gemini 0)

B(Γ) is found by adding "pushes" to B(Ω). For most of the zodiac the pushes are negative as Mercury is in retrograde.

$\delta = B(\Gamma) - B(\Omega)$

For Aries 0 $\quad \delta = 0$
From Aries 0 to Aries 15 $\quad$ increasing 0;24 per °
Aries 15 $\quad \delta = 6$
From Aries 15 to Taurus 15 $\quad$ decreasing 0;4 per °
Taurus 15 $\quad \delta = 4$
From Taurus 15 to Cancer 15 $\quad$ decreasing 0;12 per °
From Cancer 15 to Libra 15 $\quad \delta = -8$
From Libra 15 to Virgo 15 $\quad$ decreasing 0;8 per °
From Virgo 15 to Pisces 15 $\quad \delta = -12$
From Pisces 15 to Aries 0 $\quad$ increasing 0;48 per °

Or for actual computation the following system can be used:

$\lambda = B(\Omega)$	$B(\Gamma)$
Aries $0 \leq \lambda \leq$ Aries 15	Aries 0 + 1;24 λ
Aries $15 \leq \lambda \leq$ Taurus 15	Aries 21 + 0;56 (λ - Aries 15)
Taurus $15 \leq \lambda \leq$ Cancer 15	Taurus 19 + 0;48 (λ - Taurus 15)
Cancer $15 \leq \lambda \leq$ Libra 15	λ - 8
Libra $15 \leq \lambda \leq$ Virgo 15	Libra 7 + 0;52 (λ - Libra 15)
Virgo $15 \leq \lambda \leq$ Pisces 15	λ - 12
Pisces $15 \leq \lambda \leq$ Pisces 30	Pisces 3 + 1;48 (λ - Pisces 15)

T(Ξ) and T(Γ) are found by adding pushes onto T(Σ) and T(Ω). From the damaged tablet only restoration of T(Γ) was possible.

$\lambda = B(\Omega)$	$T(\Gamma) - T(\Omega)$
Aries $15 \leq \lambda \leq$ Taurus 15	38^{τ} - 0;6 (λ - Aries 15)
Taurus $15 \leq \lambda \leq$ Cancer 15	35^{τ} - 0;13 (λ - Taurus 15)
Cancer $15 \leq \lambda \leq$ Libra 15	22^{τ}
Libra $15 \leq \lambda \leq$ Virgo 15	22^{τ} - 0;16 (λ - Libra 15)
Virgo $15 \leq \lambda \leq$ Capricorn 30	14^{τ} - 0;3,12 (λ - Virgo 15)
Aquarius $0 \leq \lambda \leq$ Pisces 15	10^{τ} + 0;12 (λ - Aquarius 15)
Pisces $15 \leq \lambda \leq$ Aries 15	19^{τ} - 0;38 (λ - Pisces 15)

SYSTEM A_3

For Γ and Ω

Aries 30 to Leo 30 $\quad w1 = 0;11,6,40$
Aries 30 to Cancer 20 $\quad w2 = -0;12$
Cancer 20 to Aries 30 $\quad w3 = 0;3,16,52$

For Ξ, the loss in longitude over 1 year or 3 appearances is

From	Aquarius 0 to Gemini 30	-16°
In	Cancer and Leo	-20°
	Virgo	-28°
	Libra	-23°
	Scorpio	-18°
	Sagittarius and Capricorn	-14°

Upon examination of these systems and those for the other planets, found in ACT II, we can see that there is no procedure text which describes a system that uses a time measurement to correct the date.

Our data overlaps the periods that are covered by the preserved ephemerides contained within ACT in 19 cases, table 9. The tablets that relate to the time when our observations were made make no mention of an ideal date and instead simply follow the systems previously laid out.

Table 9. Overlaps between ideal entries and ephemerides.

Planet	Observation date	Observation position	Ideal date	Entry source	ACT date	ACT position	ACT no.
Mercury	7 XII$_2$ 18	Pisces	14	P	11	Pisces	300a
Mercury	140 IV 27	Cancer	25	P	26,9,55	Cancer	300
Mercury	140 IV 27	Cancer	25	P	22	Cancer	301
Mercury	141 III 24	Gemini	22	D V2	22,21,52	Gemini	300
Mercury	141 III 24	Gemini	22	D V2	18	Gemini	301
Mercury	147 VII 22	Libra	20	D V2	14	Libra	301
Mercury	167 VII 29	Libra	27	D V3	28	Libra	302
Mercury	168 VI 28	Virgo	24	D V3	22	Virgo	302
Mercury	176 VI 1	Virgo	V 28	G	V 16	Virgo	302
Mercury	180 XI 22	Aquarius	19	D V3	20	Aquarius	302
Mercury	188 III 19	Gemini	16	D V3	16	Gemini	302
Mercury	189 III 24	Gemini	23	D V3	12	Taurus	302
Mercury	171 XI 14	Pisces	10	D V3	12	Pisces	302
Mercury	174 IX 27	Capricorn	25	D V3	26	Capricorn	302
Mercury	141 I 15	Taurus	13	P	12	Taurus	301
Jupiter	203 V 8	Leo	7	D V3	4	Leo	611
Jupiter	215 V 26	Virgo	24	D V3	21	Leo	611
Venus	225 VII 28	Sagittarius	24	D V3	24	Sagittarius	420
Venus	208 II 16	Taurus	14	D V3	14	Taurus	420

In most cases the date from the ephemerides is earlier than both the observation and the ideal date, and except for Mercury SE 189, the positions all correlate. In four cases, Mercury 141 and 188, and Venus 208 and 225, the ideal date is the same as the date contained in the ephemerides.

For Mercury the same ephemeris covers others dates that do not match, so these two entries could simply coincide by accident with the scheme for predicting the true date. For Venus, the two cases that appear in ACT are the only two with suitable dates that they can be checked. That these dates match with our ideal dates does not necessarily mean that the ideal dates were sourced from the ephemerides as in the other 15 cases the dates do not match.

The ideal data collected does not overlap in the almanacs or NSA and could therefore not be checked.

GOAL YEAR PROCEDURE

Within Babylonian astronomy the only other entry that has a day correction occurs when creating a goal year text. A goal year text is created by collating observational datum for the required year less the period for one characteristic period from the diaries. The almanacs and NSA were made using the goal year text and adding a suitable correction for the fact that the characteristic period relation is not exactly 46 years (for Mercury).

Hunger (1999) compared the Δt correction required when using a period relation of 46 years between modern day calculation and those found in non-mathematical texts. The largest source of information when finding Δt came from comparing goal year texts and almanacs and normal star almanacs. It was found that the correction for observations was between –8 and +5 days, and for calculated data between –3 and +10 days. By modern day calculation the correction should be –1 day.

The ideal data from the texts found a range of correction from –5 days to +3 days, with an average of -2.2 days. This range is much smaller than those shown above and is closer to what the correction should be by modern calculation. But there is no evidence that the almanacs and NSA are calculated by anything but the basic scheme of day correction, i.e. no time measurement was required to determine what the correction would be. Thus we can conclude that the method for determining the ideal date was not the same as for compiling the almanacs and NSA.

IDEAL DATA

Entries concerning ideal dates for Mercury, whilst the most numerous, are unfortunately still few. Fifty-four complete entries were collected which should be examined separately for each phenomenon. This splits the entries so there are 26 for Γ, 25 for Ξ, 2 for Σ and 1 for Ω. The data from the texts found a range of correction from –5 days to +3 days.

It is possible that there are more entries correcting first visibilities as it would be easier to watch for and realise that it had appeared late as you would be watching a specific part of the sky before it had appeared. When watching for a last visibility it is possible that no notice was taken of the planet until the expected date of last visibility, which, when not observed, would only confirm that the phenomenon had occurred on the true date.

As shown in the tables 9 and 10 the data does in general show the expected trend of having a larger time measurement for a larger day correction. However there are several exceptions where this is not the case. These exceptions are not connected to any particular zodiacal signs and there are contradictions within sign too. For example for Γ, Pisces shows 15° being equivalent to a 4 day correction, however whilst it then has 14° for a 2 day correction it also has 16° for a 3 day correction. These contradictions cannot be rectified since the data base is too limited.

Table 11 shows that Σ and Ω have a positive day correction. This is to be expected, but due to the lack of data no further inferences can be made.

Table 12. Ideal data for Σ and Ω. (Ω in italics).

Year, SE	Month	Date	Position	Difference in rise times	Time measurement	Ideal date	Day correction	Source	No.
94	12	7	Aquarius	0.885	17	10	3	G	1251
125	6	1	Virgo	0.796	11	2	1	G	1269
94	10	15	Aquarius	-1.173	18	18	3	G	1251

Combining all the data for Mercury as both morning and evening star gives us a larger base with which to attempt to find trends and is shown in table 12.

Table 13. Comparison of measurement to day correction for all ideal entries.

Measurement / degrees	Average correction / days	Range of correction / days	Number of entries
11	1	1	2
12	3	3	1
14	2	2	2
14.5	2	2	2
15	2	$1 \rightarrow 4$	13
15.5	2.5	$2 \rightarrow 3$	2
16	2	$1 \rightarrow 4$	12
16.5	3	$2 \rightarrow 4$	3
17	3	$2 \rightarrow 3$	6
17.5	3	3	1
18	3.3	$3 \rightarrow 4$	3
18.5	3	$2 \rightarrow 4$	2
19	4	4	1
20	4	$2 \rightarrow 5$	4

Examination of table 12 shows the maximum day correction increasing as the measurement increases. There appear to be general blocks for upper limits on the time measurement for each day correction, however for 12°, 15.5° and 18° we see the following measurement having a lower day correction.

For the measurements of 15° and 16°, where we have a large number of entries, we have equal ranges and average day corrections. This could mean that they both reside within the same zone for the theoretical scheme but it is impossible to say for sure.

This result is not conclusive but it does allow us to place upper limits on the day corrections. Up to 11°, 1 day correction,; 12-16° 2 days correction; 16.5-18.5° 3 days correction; and 19-20° 4 days correction.

Combining the data for Mercury with data taken for other planets (table 13) we see we have a very general trend of a larger measurement with large day correction. It is much more varied than for Mercury, but this was to be expected since each planet will have a different system for calculating each phenomena.

Table 14. Ideal data for all the planets combined.

Measurement / degrees	Average correction / days	Range of correction / days	Number of entries
8.33	1	1	1
8.5	3	2 → 4	2
9	3.2	3 → 4	5
9.5	2	2	2
10	2.25	1 → 4	4

20.5	4	4	1
21	3	3	1
22	13	13	1
30	5.33	4 → 7	3

NORMAL STARS

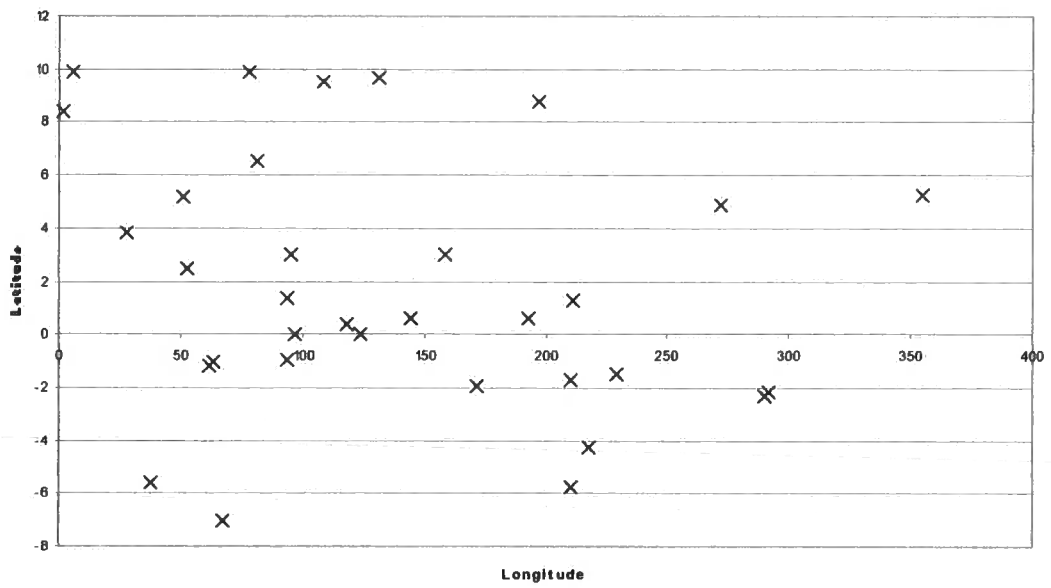
When sourcing the data to investigate acronycal risings and ideal dates it was necessary to translate the planetary texts, which could later be checked against Hermann Hunger's translations[41], almanacs and normal star almanacs.

During the translation of these it was necessary to compile a 'star catalogue'. This has been done before but not with a cuneiform description as well. The ultimate number of stars the Babylonians used is for debate, with Sachs (1974) listing 31 and Hunger and Pingree[42] 32, to name but a couple.

During my reading I needed 33 star names to fully translate all the entries I required. These were obtained using an initial list by Hunger[43] and then examining his translations for a diary containing the appropriate star so that the cuneiform could be obtained from examination of the relevant plate. It is by no means a complete listing of all the stars in the Babylonian zodiac but merely the ones I found useful to obtain and use.

Figure 14 is a plot of these 33 stars. It shows their distribution across the sky and zodiac (by longitude). It is apparent that they are not evenly distributed and there are gaps of up to 50° by longitude.

Figure 14. A plot of the 33 normal stars.



The cuneiform and Akkadian descriptions of the stars are given in their fullest form. However upon examination of the tablets it is seen that they are often shortened. For example in the entry[44]

> SAG GE_6 sin ina IGI ŠUR SI 2 K[ÚŠ...]
> beginning of the night, the moon was 2 cu[bits] in front of β Tauri

The description for β Tauri uses ŠUR SI as opposed to the full ŠUR GIGIR šá SI .

[41] ADT V5.
[42] ASM.
[43] ADT V1, 17-19.
[44] ADT V3, 53.

Also for each of the Akkadian signs there are often variations. The ones listed here are simply the most common.

These star names, and the entries recording conjunctions with them can be used to follow the path of a planet over several cycles much more accurately than if it were identified only by zodiacal sign.

Figure 15 is a plot using entries[45] recording Mercury's position by a specific star. The lines plotted through the points, whilst being a trendline, can be used as the ecliptic, this being the path the sun takes. The data fluctuates around this line in the same way we would expect for a graph displaying the daily motion of Mercury. It shows that this format of recording a planetary position is very accurate.

Figure 15. Plot to show Mercury's daily motion using entries noting passings by the normal stars.

SUMMARY

The main findings of this thesis are therefore as follows.

For determining the true meaning of Θ, one of the Greek letter phenomena, after following the presumption throughout literature since 1889 we have proved through examination of the texts of Babylonian astronomy that it relates to acronycal rising.

Evidence in the texts of mathematical astronomy show that for examples for Mars and Jupiter Θ occurs closer to closer to Φ than to Ψ which means that Θ has an elongation from the sun of less than 180° and is therefore an acronycal rising.

Evidence from the texts of non mathematical astronomy was examined for the outer planets by source then by planet, and then for Sirius. Due to the lack of data in other sources, conclusions can only be drawn for the diaries and planetary texts. The majority of their points are below 180° and for an opposition we would expect an even distribution above and below 180°. For these two sources it would therefore appear that Θ does in fact mean acronycal rising.

The results for Jupiter will be the most confident since it has by far the most amount of data. It indicates that Θ should be read as acronycal rising and is confirmed by the Mars data. Whilst it would at first appear that there is a problem with Saturn, since the average is over 180°, the values from the normal star almanacs are extreme. The fact that Saturn's elongation at Θ is greater for the predictions in the normal star almanacs than the observations in the diaries, confirms that too small a correction to the goal year period was often applied. It also indicates that the goal year periods were in actual fact used to compile the normal star almanacs. Thus for Saturn the results can be explained and still prove the case for Θ being an acronycal rising.

Data collated for Sirius shows that $\lambda_{\odot}$-λ_{Sirius} ranges from 203-207°. The data varies only over 4° in 300 years, which could be expected since Sirius does in fact move along the zodiac, although very slowly, less than 3° in 300 years. Since Sirius is located a long way from the ecliptic it has quite a large negative latitude, about -37° for the years with the necessary data. This forces the characteristic phenomena of Sirius to occur in an abnormal order. Since Θ_2 occurs before Θ_1, the elongation for an acronycal rising will in fact occur with an elongation greater than 180°, and acronycal setting less than 180°. Thus the collected data matches with what we would expect for Θ_1 for Sirius.

The other main part of this thesis investigates the ideal dates of planetary phenomena. Amongst observational records there are often comments regarding an unexpected observation or not observing a phenomenon that was expected. Unexpected observations contain a time measurement between the unexpectedly observed phenomenon and the rising/setting of the sun, accompanied with a date when the phenomenon should have occurred. Of all the information collected the greatest portion was for Mercury, thus Mercury was examined and then all the planets together.

Theoretical systems for Mercury work on the basic premise that 145 occurrences of the same phenomenon occur in 46 years. The systems are all are of type A and so use step functions of the position in the ecliptic. There are variations between each system due to distributions of the zones for each phenomena. However none of the systems use the time difference between the setting of the sun and rising of Mercury within the method. Upon examination of these systems for the other planets, found in ACT II, we can see that there is again no procedure text which describes a system that uses a time measurement to correct the date.

Examples of ideal data from the texts found a range of correction from –5 days to +3 days, with an average of -2.2 days. This range is much smaller than those for goal year texts created using almanacs and normal star almanacs and is closer to what the correction should be by modern calculation. But there is no evidence that the almanacs and NSA are calculated by anything but the basic scheme of day correction, i.e. no time measurement was required to determine what the correction would be. Thus we can conclude that the method for determining the ideal date was not the same as for compiling the almanacs and NSA.

Entries concerning ideal dates for Mercury were collected and examined separately for each phenomenon. There are 26 for Γ, 25 for Ξ, 2 for Σ and 1 for Ω. The data from the texts found a range of correction from –5 days to +3 days. This result is not conclusive but it does allow us to place upper limits on the day corrections. Up to 11°, 1 day correction; 12-16° 2 days correction; 16.5-18.5° 3 days correction; and 19-20° 4 days correction.

Combining the data for Mercury with data taken for other planets there is very general trend of a larger measurement with large day correction. It is much more varied than for Mercury, but this was to be expected since each planet will have a different system for calculating each phenomena. Due to the lack of data however, no specific limits could be placed.

IDEAL ENTRIES FOR MERCURY

Year, SE	Month	Date	Position	Difference in rise times	Time measurement	Ideal date	day correction	Source	Page	Comments
AR III 12	10	2	Sagittarius	1.286	20	IX 29	-4	D V1	145	Date 1-4, measurement for rising of Mercury to sunrise=first appearance in east.
AR II 44	6	24	Virgo	-0.818	18	21	-3	P	249	First appearance in east, it was bright.
AR II 44	3	10	Gemini	-1.026	19	6	-4	P	249	First appearance in east, it was bright.
7	13	18	Pisces	-2.135	15	14	-4	P	283	First appearance in east.
22	4	7	Cancer	1.774	18.5	5	-2	D V1	279	First appearance in east.
48	11	10	Aquarius	0.675	17	7	-3	P	297	First appearance in east.
74	4	23	Cancer	1.604	17	21	-2	D V2	89	First appearance in east, it was high.
79	8	28	Scorpius	-1.590	17	26	-2	D V2	107	First appearance in east.
94	4	26	Cancer	0.736	15	25	-1	G	1251	First appearance in east.
102	4	9	Gemini	1.705	18.5	5	-4	D V2	185	First appearance in east, it was bright and high.
110	10	13	Sagittarius	-0.987	20	8	-5	D V2	219	First appearance in east, it was bright and high.
114	11	14	Aquarius	0.716	15	12	-2	D V2	249	First appearance in east, it was bright.
114	7	19	Libra	-13.494	16	17	-2	D V2	243	First appearance in east, it was bright.
140	4	27	Cancer	0.370	20	25	-2	P	345	First appearance in east, it was bright and high.
141	3	24	Gemini	-0.074	16	22	-2	D V2	453	First appearance in east, it was bright and high.
147	7	22	Libra	0.877	15	20	-2	D V2	495	First appearance in east, it was bright and high.
167	7	29	Libra	-1.403	17	27	-2	D V3	95	First appearance in east, date after 26th.

Year, SE	Month	Date	Position	Difference in rise times	Time measurement	Ideal date	day correction	Source	Page	Comments
168	6	28	Virgo	-0.044	18	24	-4	D V3	109	First appearance in east, date after 26, it was bright and high.
176	6	1	Virgo	1.218	17	28 of V	-3	G	1294	First appearance in east, 2 cubits 8 fingers in Virgo.
180	11	22	Aquarius	0.460	17.5	19	-3	D V3	237	First appearance in east, it was bright.
188	3	19	Gemini	1.626	16.5	16	-3	D V3	281	First appearance in east, it was bright and high.
189	3	24	Gemini	-0.623	11	23	-1	D V3	295	Probably Gemini, time for rising of Mercury to sunrise=first appearance in east.
224	13	17	Pisces	0.028	14	15	-2	D V3	455	First appearance in east in end of Pisces, date 16-17, it was small.
225	8	1	Scorpius	-1.180	16	VII 28	-4	D V3	461	First appearance in east, it was bright.
234	3	18	Gemini	1.701	16	16	-2	D V3	491	First appearance in east, it was small.
258	11	18	Pisces	-0.512	16	15	-3	P	357	First appearance in east in beginning of Pisces, date uncertain, in translation [x]+18.
8	2	6	Gemini	1.925	16	4	-2	P	283	First appearance in west.
38	8	21	Sagittarius	0.455	16	19	-2	D V1	341	First appearance in west.
45	4	9	Cancer	-1.091	15	7	-2	G	1220	First appearance in west.
50	9	20	Capricorn	-0.993	15	18	-2	D V1	375	First appearance in west, bright and high, ideal on 19th or 18th.
55	10	12	Capricorn	1.591	15	9	-3	P	307	First appearance in west in end of Capricorn, it was bright and high.
56	12	22	Taurus	0.392	16.5	20	-2	P	309	First appearance in west in beginning of Taurus, it was bright.
84	12	4	Aries	0.523	14.5	2	-2	P	321	First appearance in west in beginning of Aries, it was bright.

119	2	18	Gemini	-1.858	15	16	-2	D V2	293	First appearance in west, it was bright and high.
125	11	14	Virgo	-1.122	16	12	-2	D V2	343	First appearance in west, it was bright and high.
128	10	15	Capricorn	0.985	15.5	13	-2	G	1285	First appearance in west.
143	5	27	Virgo	2.007	16	25	-2	D V2	471	First appearance in west sic, time for rising of Mercury to sunrise.
171	11	14	Pisces	2.258	16.5	10	-4	D V3	157	First appearance in west, it was bright and high.
174	9	27	Capricorn	1.372	14.5	25	-2	D V3	169	First appearance in west, it was bright and high.
176	4	2	Leo	-1.155	15	1	-1	G	1294	First appearance in west.
178	6	21	Pisces	-0.879	15	20	-1	D V3	203	First appearance in west in beginning of Pisces, it was bright.
179	2	8	Gemini	-1.721	15.5	5	-3	D V3	211	First appearance in west, date 8-9, it was bright.
202	9	10	Capricorn	-0.996	12	7	-3	D V3	351	First appearance in west, date 9-12 , ideal in Sagittarius, it was bright.
234	5	13	Virgo	0.687	16	12	-1	D V3	495	First appearance in west, it was small.
258	10	15	Aquarius	-0.844	15	13	-2	P	357	First appearance in west in beginning of Aquarius.
259	2	2	Gemini	-0.933	16	1	-1	P	357	First appearance in west.
A IV 8	6	3	Libra	0.263	14	1	-2	D V1	237	First appearance in west.
A IV 8	1	19	Taurus	-0.836	20	16	-3	D V1	233	First appearance in west.
AR II 38	3	10	Leo	1.150	16	8	-2	D V1	133	First appearance in west.

Year, SE	Month	Date	Position	Difference in rise times	Time measurement	Ideal date	day correction	Source	Page	Comments
94	12	7	Aquarius	0.885	17	10	3	G	1251	In east, ideal in Pisces, positive day correction so last appearance in east.
125	6	1	Virgo	0.796	11	2	1	G	1269	Last appearance in east, by alpha Virginis.
94	10	15	Aquarius	-1.173	18	18	3	G	1251	Last appearance in west, ideal in Aquarius.
152	11	1	Pisces		14			G	1287	First appearance in west in start of Pisces.
138	8	17	Scorpius		14			P	343	First appearance in east, it was bright, date uncertain.
56	6	2	Virgo		14.5			D V2	25	First appearance in west.
AR II 44	9	6	Capricorn		17			P	249	First appearance in west, it was bright.
152	8	14	Scorpius		17.5			G	1287	First appearance in east
120	8	7	Libra		21			D V2	301	First appearance in east in end Libra, date 6-8, it was bright and high.
49	11	2	Capricorn		22			G	1223	First appearance in east.
9	2	2	Gemini			-2	-4	P	283	First appearance in west in beginning of Gemini.
AR II 29	8	7	Libra			6	-1	P	207	First appearance in east, it was high
200	1	10	Taurus			8	-2	D V3	337	First appearance in west.
AR II 41	8	10	Scorpius			8	-2	P	241	First appearance in east, it was high.
226	10	11	Aquarius			9	-2	D V3	465	First appearance in west, ideal in beginning of Aquarius.
AR II 25	12	12	Aries			11	-1	P	205	First appearance in west, it was bright.
23	13	16	Aries			13	-3	D V1	283	First appearance in west.
161	7	14				13	-1	G	1291	First appearance in the east.
141	1	15	Taurus			13	-2	P	345	First appearance in west, it was bright.

Year, SE	Month	Date	Position	Difference in rise times	Time measurement	Ideal date	day correction	Source	Page	Comments
AR II 43	11	20	Aquarius			16	-4	P	247	First appearance in east, it was bright and high.
157	11	21	Aquarius			18	-3	D V3	79	First appearance in west in end of Aquarius, measurement 10+x.
AR II 32	4	26	Leo			19	-7	D V1	113	First appearance in west, no measurement.
AR II 31	7	25	Scorpius			20	-5	D V1	105	Last part of night, ideal around 20th.
AR III 15	1	23	Pisces			21	-2	D V1	157	First appearance in west, date 22-24.
175	10	25				21	-4	D V3	187	First appearance, date 25-26.
AR II 41	4	27	Leo			21	-6	P	241	First appearance in east, it was small.
122	6	26	Virgo			24	-2	D V2	319	First appearance in east.
193	1	30	Gemini			27	-3	D V3	321	First appearance in west in beginning of Gemini, ideal in end of Taurus, it was bright and high.
85	11	29	Pisces			27	-2	P	321	First appearance in west.
128	4	1	Gemini			III 26	-5	D V2	363	First appearance in east, date 1-2.
AR II 44	5	2	Virgo			IV 27	-7	P	249	First appearance in west.
AR II 25	10	1	Sagittarius			IX 27	-4	P	205	First appearance in west, in end of Sagittarius, it was high.
84	6	3	Virgo			x		P	321	First appearance in east, it was bright and high, didn't watch the time interval.
AR II 44	1	2	Taurus			XII2 25	-7	P	247	First appearance in west in front of Alpha Tauri, it was bright and high.

IDEAL ENTRIES FOR JUPITER.
